

Locking Away Prosperity? Evaluating the Labor Impacts of Vaccine Mandates

1 Introduction

The COVID-19 pandemic triggered a global wave of non-pharmaceutical interventions (NPIs) as governments acted swiftly to limit viral transmission. Much early research focused on the public health rationale for these policies—especially the importance of early action to contain exponential spread. For instance, [Friedson et al. \[2021\]](#) and [Yang \[2021\]](#) use synthetic control methods to evaluate lockdowns in California and Wuhan, emphasizing the critical role of timing. Similarly, [Bayat et al. \[2020\]](#) estimate that New York City could have reduced COVID-19 deaths by over 80% had its first lockdown occurred just ten days earlier. Subsequent work examined the economic consequences of such interventions. While NPIs helped flatten the curve, they also raised concerns about business closures, layoffs, and lasting economic scarring. Studies like [Gibson and Sun \[2023\]](#) and [Lee and Yang \[2022\]](#) document labor market costs of lockdowns, while [Ke and Hsiao \[2022\]](#) show that although strict NPIs incur short-term economic losses, those effects may be temporary.

By 2021, as vaccines became widely available, cities such as New York City (NYC), New Orleans (NOLA), Los Angeles (LA), and San Francisco (SF) turned to vaccine mandates as a less restrictive (but still controversial) tool for curbing transmission.¹ Unlike lockdowns, mandates aimed to sustain economic activity in industry while reducing health risks in high-contact settings. Nevertheless, critics argued that requiring proof of vaccination for indoor dining and entertainment could slow employment recovery in restaurants by alienating customers or exacerbating staffing shortages [\[Dive, 2021\]](#). Supporters countered that mandates would improve public safety and restore consumer confidence, potentially boosting demand and employment [\[Jones, 2021\]](#).

Each city’s mandate differed in timing and design. NYC’s *Key to NYC* program, announced in August 2021 and enforced beginning September, was the first large-scale vaccine mandate for indoor commerce in the United States [\[Fortney, 2021\]](#). San Francisco followed with an even stricter rule requiring full vaccination for customers and employees, effective later that same month [\[Duffett, 2021\]](#). New Orleans adopted a hybrid approach, permitting either proof of vaccination or a recent negative test [\[Lorell, 2021\]](#), while Los Angeles—by far the largest jurisdiction—implemented its policy in November [\[Reyes, 2021\]](#). These mandates created a

¹Henceforth, I refer to these simply as the treated units

small but consequential set of urban outliers in the national policy landscape, with important implications for labor markets in the leisure and hospitality sector. Precisely, the estimated effects of city-level vaccine mandates on restaurant employment suggest several potential lessons for policymakers and business stakeholders. If the mandates support employment growth, policymakers could view them as a viable tool for balancing public health and economic activity. Cities considering similar interventions might adopt comparable policies with confidence that labor markets will not be severely disrupted. Businesses could plan for future public health policies with reduced concern for employment losses in high-contact sectors. If the mandates depress employment, policymakers should weigh the trade-offs more carefully before implementing mandates, especially in sectors sensitive to consumer demand and staffing shortages. Alternative interventions, such as targeted incentives for vaccination, improved workplace safety measures, or temporary subsidies, might be preferable to blunt employment impacts of mandates. Businesses may need mitigation strategies, including flexible staffing or remote services, to reduce vulnerability to future mandates. If the effects are heterogeneous across cities, differences in local conditions such as compliance rates, labor market tightness, or enforcement intensity should guide tailored policy decisions rather than blanket mandates. Comparative case studies could help identify which contextual factors drive positive versus negative outcomes.

This paper evaluates the causal effects of these city-level vaccine mandates on restaurant employment. While prior research has analyzed mandates’ impacts on vaccination rates and health outcomes [Cohn et al., 2022, Acharya and Dhakal, 2021, Lang et al., 2023], relatively little is known about their labor market consequences, especially in industries dependent on face-to-face interaction. This study helps fill that gap. Because randomized experiments are infeasible, the analysis adopts a synthetic control approach to estimate the counterfactual trajectory of restaurant employment absent the mandates. Using MSA-level monthly data from the Federal Reserve Bank of St. Louis, I construct synthetic controls for each mandate city’s year-over-year growth in full-service restaurant employment. The donor pool consists of metropolitan areas that did not implement similar mandates during the same period.²

The rest of the paper is organized as follows. Section 2 provides background on the evolution of pandemic interventions and the city-level vaccine mandates. Section 3 describes the employment data and outcome construction. Section 4 outlines the empirical strategy, including the synthetic control methodology. Section 4.2 presents the main findings and robustness checks. Section 5 interprets the results and discusses limitations. Section 6 concludes.

²For example, ‘SMU11000007072251101SA’ (Washington, DC) or ‘SMU08197407072251101SA’ (Denver MSA).

2 Policy Background

Timeline of major pandemic policy phases

2.1 NPIs Before Vaccines

NPIs had aimed to reduce transmission by limiting contact or promoting respiratory barriers. The first and most famous of these interventions was the 2020 lockdown in Wuhan, China, where local officials went as far as to forcibly seal people in their homes to reduce the possibility to spread the virus; similar actions were taken in Europe and India. Even in the United States, states that could effectively seal their borders, such as Hawaii, did so, with Hawaii mandating two-week quarantines to visitors, which effectively amounted to a tourism ban. Mask mandates were widely adopted as well due to their low cost and direct mechanism of action [Hansen and Mano, 2023, Chernozhukov et al., 2021, Mitze et al., 2020]. While not as severe as lockdowns, the idea of mask mandates was to allow for some freedom of movement while minimizing the chance to spread the virus further. While both sets of policies were effective, they still provoked political backlash due to their perceived disruptive nature (especially in the United States).

2.2 The First Vaccine Policies

The arrival of vaccines in late 2020 ushered in a new phase of pandemic governance, giving jurisdictions a wider array of policy options to employ. Now, instead of lockdowns, governments finally had pharmaceutical interventions in their toolkit. Unlike non-pharmaceutical interventions, which sought to reduce transmission primarily by altering citizens behavior and limiting contact (and therefore the spread of the virus), vaccine-based interventions operate directly on biological susceptibility. NPIs such as lockdowns, mask mandates, and border closures work by creating external barriers to viral spread, often imposing economic or social costs in the process. Vaccine mandates, by contrast, rely on an individual’s immune response to prevent infection or reduce severity, aiming to achieve population-level protection without requiring broad restrictions on mobility or commerce. In principle, this allows policymakers to target public health objectives more directly, potentially mitigating the trade-offs between controlling the virus and maintaining economic activity. Nevertheless, vaccine-based mandates introduce new challenges, including compliance, equity, and political acceptability, which differ in character from those associated with NPIs.

For the first few months, it worked: when vaccines were released, initial uptake was high, particularly among older adults and (often mandated for) healthcare workers [?]. However, as eligibility expanded in early 2021, demand slowed amid misinformation, mistrust, and logistical barriers. In response, policymakers deployed incentive-based strategies to encourage vaccination [Barber and West, 2022, Robertson et al., 2021]. These included direct cash payments, vaccine lotteries (e.g., Ohio’s “Vax-a-Million” from May to June [Fuller et al., 2022]), and smaller symbolic giveaways. One paper dubbed this the era of “donuts, drugs, booze, and guns,” reflecting the extraordinary lengths to which governments went to boost uptake through rewards rather than requirements [Tinari and Riva, 2021].

Despite their creativity, most incentives had modest or short-lived effects [Saban et al., 2021, Walkey et al., 2021, Khazanov et al., 2023]. Many were poorly targeted, administratively complex, or insufficient to overcome deeper resistance. The emergence of the highly transmissible Delta variant in mid-2021 raised the stakes. Initially identified in India, Delta reached the United States by May and accounted for the majority of new cases by June. Unlike in 2020, officials now had vaccines at scale—but not enough vaccinated people. Given a new more contagious strain, soft mandates emerged, targeting workers in high-risk occupations such as healthcare and education. These policies were not general mandates but did make vaccination a condition of continued employment [American Medical Association et al., 2021]. Over the summer, local governments and organizations expanded this approach [American Medical Association et al., 2021, Al Jazeera, 2021].

2.3 City-Level Vaccine Mandates

The summer 2021 Delta surge spurred several major U.S. cities to enact vaccine verification requirements for indoor restaurants and leisure venues. Each city’s approach differed slightly in timing and scope, but all shared the common goal of linking access to indoor leisure activities with proof of vaccination. Together, the treated units formed the clearest urban experiments in the use of vaccine mandates to manage both public health risks and consumer confidence in the hospitality sector.

New York City’s “Key to NYC” program was the first such mandate in the United States. Announced on August 3, 2021, formalized on August 16, and enforced beginning September 13, it required proof of at least one vaccine dose to enter indoor dining, fitness centers, and entertainment venues [Benveniste, 2021]. Importantly, the rule applied not only to patrons but also to employees of covered establishments. This dual requirement meant that the policy had the potential to affect restaurant employment through both the supply side, if workers resisted vaccination or exited the industry, and the demand side, if consumer traffic shifted in response to the mandate. The city threatened fines for noncompliance and required businesses to post signage and maintain written protocols, though the intensity of inspections varied. Large chains tended to comply quickly [Messenger, 2021], while smaller establishments voiced concern about administrative burdens and customer pushback. Several lawsuits challenged the mandate, but city officials argued that rising vaccination rates demonstrated its effectiveness [Wiener-Bronner, 2021]. San Francisco followed closely, enacting its mandate on August 20, 2021. Unlike New York, the city required full vaccination rather than just one dose, and did not allow a testing alternative [San Francisco, 2021, Duffett, 2021]. This made San Francisco’s

policy the strictest among the four cities. The requirement extended to both customers and employees in indoor restaurants, bars, and entertainment venues. Enforcement included spot checks and the threat of fines, with compliance reported to be widespread among larger businesses in the city’s dense urban core. As in New York, officials promoted the policy as a tool for stabilizing consumer confidence in public spaces, even as smaller businesses expressed anxiety about turning customers away.

New Orleans became the first major city in the South to adopt a mandate, announcing its policy on August 16, 2021. The city’s approach was a hybrid model: individuals could gain entry to indoor restaurants and venues either by showing proof of at least one vaccine dose or by presenting a recent negative COVID test [Aya and Riess, 2021]. This flexibility reflected local political and cultural dynamics but also introduced more administrative complexity for restaurants. Enforcement began within weeks [Just, 2021a,b], with inspections carried out by city officials. Restaurant owners reported mixed reactions, with some noting relief that the policy might make indoor dining safer, while others expressed concern about deterring unvaccinated tourists and residents [Chavez, 2021]. Los Angeles entered the field later, passing its ordinance in October 2021 with enforcement beginning November 4. The policy was sweeping in scope, covering indoor restaurants, gyms, theaters, salons, and other leisure establishments. By the time it came into effect, public debate had already been shaped by the experience of New York and San Francisco, and Los Angeles became the largest jurisdiction in the nation to implement a vaccine passport [Solis and Branson-Potts, 2021].

Although the four cities differed in timing and strictness, they shared important common features. Each policy was applied citywide, targeted indoor leisure and hospitality settings, and created new compliance responsibilities for businesses. They also diverged sharply from the policy environments of states such as Texas and Florida, which prohibited vaccine requirements altogether. The result was a small cluster of urban outliers using vaccine mandates as a central public health intervention in 2021. These institutional details carry important implications for research design. Because the mandates covered both patrons and employees in most cases, they may have constrained labor supply by excluding some workers while simultaneously influencing labor demand by shaping customer traffic. Enforcement intensity and public perception varied, but each policy represented a reasonably sharp and well-documented intervention, announced and enforced on a specific timeline. This combination makes them suitable for empirical evaluation. Comparing employment outcomes in these cities against synthetic control groups of metropolitan areas without mandates offers a credible way to estimate causal effects on restaurant employment. The staggered adoption across cities and the variation in stringency further enrich the research design, providing multiple natural experiments within a single policy family.

2.4 The First Vaccine Mandates

Per the above, vaccine mandates could influence employment in full-service restaurants through both supply- and demand-side channels, with theoretically ambiguous net effects. On the supply side, some workers may exit the labor force or shift sectors if unwilling to comply, especially in lower-wage service jobs where vaccine hesitancy may be higher. However, others may comply with the mandate precisely *because* they wish to keep their jobs,

choosing continued employment over personal objection. That is, the employment effect may hinge less on individual preferences in isolation and more on the strength of the economic incentives at stake. Employers, meanwhile, may face frictional costs from enforcing mandates or accommodating staffing turnover. On the demand side, mandates may increase consumer confidence by signaling a safer environment, thereby encouraging more patrons to return to indoor dining. For a sector like full-service restaurants, where both interpersonal contact and discretionary spending are central, mandates could plausibly stimulate demand even as they introduce short-run supply constraints. Whether employment rises or falls in net depends on which margin dominates. In short, this analysis seeks to quantify the net effect of the mandate on restaurant employment, capturing the balance between these potentially opposing forces.

3 Dataset

We use monthly MSA-level employment series from the Federal Reserve Bank of St. Louis (FRED) and, by extension, the Bureau of Labor Statistics, spanning January 1991 through December 2022, yielding $T = 384$ monthly observations per unit. Let $\mathcal{J} = \{1, \dots, J\}$ denote the set of treated units, corresponding to New York City, San Francisco, New Orleans, and Los Angeles. For treated unit $j \in \mathcal{J}$, the pre-treatment period is defined as

$$\mathcal{T}_1^{(j)} = \{t \in \mathbb{N} : t \leq T_0^{(j)}\},$$

where $T_0^{(j)}$ is the final period before the mandate in city j . Similarly, the post-treatment period is

$$\mathcal{T}_2^{(j)} = \{t \in \mathbb{N} : t > T_0^{(j)}\}.$$

Our analysis focuses on two related outcome sets: (1) full-service restaurant employment for the treated cities and 30 additional MSAs, and (2) broader leisure industry employment at the MSA level for approximately 255 MSAs from 1991 to December 2022.

Let e_{jt} denote employment in unit j at month t , and define the year-over-year growth rate in percentage points as

$$y_{jt} = 100 \cdot \frac{e_{jt} - e_{j,t-12}}{e_{j,t-12}}, \quad j = 1, \dots, N, \quad t = 13, \dots, T,$$

using smoothed and seasonally adjusted values. Outcomes for each unit are collected into vectors $\mathbf{y}_j = (y_{j1}, \dots, y_{jT})^\top$.

For each treated city $j \in \mathcal{J}$, a separate synthetic control is estimated using a donor pool

$$\mathcal{N}_0^{(j)} = \mathcal{N} \setminus (\{j\} \cup \mathcal{J} \setminus \{j\}),$$

which excludes the treated unit itself as well as the other treated units. The treatment indicator is now

$$d_{jt} = \mathbf{1}\{j \in \mathcal{J} \wedge t > T_0^{(j)}\},$$

so observed outcomes satisfy

$$y_{jt} = (1 - d_{jt})y_{jt}(0) + d_{jt}y_{jt}(1),$$

with causal effects

$$\tau_{jt} = y_{jt}(1) - y_{jt}(0).$$

The post-treatment average treatment effect on the treated (ATT) is

$$\text{ATT} = \frac{1}{J} \sum_{j \in \mathcal{J}} \frac{1}{|\mathcal{T}_2^{(j)}|} \sum_{t \in \mathcal{T}_2^{(j)}} \tau_{jt},$$

averaging first over the post-treatment months within each city and then across all treated cities.

4 Econometric Methodology

4.1 Classical Synthetic Control Method

The Synthetic Control Method (SCM), introduced by ? and extended by ?, constructs a counterfactual for a treated unit as a weighted average of untreated donor units. For treated unit j , let $\mathbf{y}_j^{\mathcal{T}_1}$ denote the vector of pre-treatment outcomes and $\mathbf{Y}_0^{\mathcal{T}_1}$ the matrix of pre-treatment outcomes for the donor pool. The classical SCM finds the optimal weights $\mathbf{w}_j$ by solving

$$\mathbf{w}_j^{\text{SCM}} = \underset{\mathbf{w} \in \mathcal{W}_{\text{conv}}}{\text{argmin}} \left\| \mathbf{y}_j^{\mathcal{T}_1} - \mathbf{Y}_0^{\mathcal{T}_1} \mathbf{w} \right\|_2^2$$

subject to $\mathbf{w} \geq \mathbf{0}$ and $\mathbf{1}^\top \mathbf{w} = 1$, where $\mathcal{W}_{\text{conv}}$ is the probability simplex. The resulting synthetic control is used to generate the post-treatment counterfactual:

$$\hat{y}_{jt}(0) = \mathbf{Y}_{0t} \mathbf{w}_j^{\text{SCM}}, \quad t > T_0^{(j)}.$$

The treatment effect at time t is then estimated as $\hat{\tau}_{jt} = y_{jt} - \hat{y}_{jt}(0)$.

While classical SCM performs well when a convex combination of donors closely matches the treated unit's pre-treatment trajectory, it produced inadequate pre-treatment fit in this

application. The unique characteristics of large, coastal, tourism-dependent cities often place them near or outside the convex hull of the donor pool (other MSAs). Poor pre-treatment fit weakens confidence in the post-treatment counterfactuals.

4.2 Partially Pooled Synthetic Control

To address this limitation while exploiting the similarity across the four treated cities, I implement a **partially pooled synthetic control estimator**. This method jointly estimates donor weights across the treated units, allowing controlled information sharing among New York City, San Francisco, New Orleans, and Los Angeles, which faced similar vaccine mandate policies targeting the leisure and hospitality sector during the 2021 Delta variant wave.

Let $\mathbf{Y}_1 \in \mathbb{R}^{T \times J}$ be the outcome matrix for the $J = 4$ treated cities and $\mathbf{Y}_0 \in \mathbb{R}^{T \times N_0}$ the donor matrix. The estimator solves for a weight matrix $\Theta \in \mathbb{R}^{N_0 \times J}$ (each column contains the donor weights for one city) and a vector of city-specific intercepts $\alpha \in \mathbb{R}^J$.

The procedure consists of two steps. First, a pooling intensity parameter $\nu \in [0, 1]$ is estimated from the pre-treatment data. This parameter determines the relative weight placed on fitting each city separately versus fitting them jointly. It is computed by comparing the mean squared errors from fully separate SCM estimations against a pooled estimation (see Appendix for details). A value of ν close to 1 implies strong pooling (similar donor weights across cities), while a value close to 0 allows nearly independent weights for each city.

Second, the estimator minimizes the following objective function:

$$(1 - \nu) \cdot \left(\frac{1}{J} \sum_{j=1}^J \|\mathbf{M}_j \odot (\mathbf{y}_j - \mathbf{Y}_0 \boldsymbol{\theta}_j - \alpha_j \mathbf{1})\|_2^2 \right) + \nu \cdot \left(\frac{1}{T^*} \sum_t \bar{r}_t^2 \right) + \lambda \|\Theta\|_F^2$$

subject to $\Theta \geq \mathbf{0}$ and $\mathbf{1}^\top \boldsymbol{\theta}_j = 1$ for each column j . Here, $\mathbf{M}_j$ is a binary mask selecting pre-treatment periods for city j , $\bar{r}_t$ denotes the average residual across treated cities at time t (among those still in the pre-treatment window), and $\lambda > 0$ is a small ridge regularization term that stabilizes the solution.

This partially pooled approach offers important advantages. It borrows statistical strength across the four related policy experiments, often yielding better pre-treatment fit than separate SCMs. It naturally accommodates staggered treatment timing across cities. Additionally, the data-driven estimate of ν reveals the degree of commonality in how the mandates influenced restaurant employment dynamics.

Counterfactuals generated from this estimator are used to compute city-specific treatment effects as well as an overall average treatment effect on the treated (ATT), calculated by first averaging post-treatment gaps within each city and then across the four cities. Inference relies primarily on placebo tests, in which each donor MSA is iteratively assigned a placebo treatment and the distribution of placebo effects is compared to the estimated effects for the treated cities.

All estimations use year-over-year growth rates (in percentage points) of full-service restaurant employment to remove seasonality and long-term trends. Robustness checks include alternative donor pools, broader leisure and hospitality employment measures, and sensitivity to the regularization parameter λ . Full implementation details and code for the partially pooled estimator are provided in the Appendix.
